ABSTRACT: Despite numerous investigations devoted to the control of peptide and protein self-assemblies using nanostructured materials, the molecular details of the peptide-material interaction sites remain still under debate. Here, we suggest a solution by using jointly the middle- and low wavenumber regions of surface-enhanced Raman spectra. To achieve our goal, adequately prepared gold and silver colloids, of which the nanofabrication was controlled by means of zeta potential and extinction spectra, were used to enhance the Raman signal arising from a natural fibrillogenic peptide hormone, somatostatin-14, at very low (10^{-6}-to-10^{-8} M) concentrations. Transmission electron microscopy has revealed that the interacting partners are involved in a mutual aggregation process. In fact, while the presence of plasmonic colloids facilitates the aggregation of the peptide, leading to the formation of the so-called "corona" around nanoparticles, we could observe the appearance of relatively large size peptide-nanoparticle agglomerates in solution. However, the comparison between the data obtained from gold and silver nanoparticles is consistent with the fact that the nature of metal surface, as well as its ionic coverage, considerably affect the peptide binding and subsequent aggregation process. Furthermore, this work led us to conclude that the adsorption of somatostatin-14 on silver nanoparticles is rendered possible through an ionic pair interaction, whereas its anchoring on gold nanoparticles occurs by a direct binding, in which the metal atom and the nitrogen of the unique peptide tryptophan residue are involved.
■ INTRODUCTION

Primarily elaborated for their remarkable physicochemical features, nanoparticles (NPs) have rapidly been identified for their possible applications in the fields of biology and medicine.[1] NPs are basically appreciated for their large surface/volume ratio, offering them the possibility to be employed either for accelerating or for inhibiting certain biological processes. In this framework, a series of reports have highlighted the use of selected NPs for controlling protein self-assemblies taking part in human amyloid disorders.[2−6] To mention a few characteristic examples, we can emphasize the application of (i) organic NPs of NIPAM/BAM copolymer for accelerating the aggregation of human β2-microglobulin protein,[7] (ii) inorganic NPs, such as those elaborated either from CdTe for preventing the fibrillation,[8] or from uniform maghemite γ-Fe$_2$O$_3$ NPs for accelerating/inhibiting the fibrillation[9] of amyloid β (Aβ) peptides involved in Alzheimer's
disease, and (iii) metallic gold NPs which have shown a large spectrum of action including the inhibition of the aggregation of short size Aβ peptides,[10] the acceleration of fibrillation of cysteine-free peptides,[11] and finally, the retardation of insulin fibrillogenesis process.[12]

Taking into account the large enhancement of the electromagnetic radiation induced by the so-called plasmon resonance effect, we focus here on gold and silver NPs and their particular use in surface-enhanced Raman spectroscopy (SERS). This spectroscopic technique is widely used for its ability to detect very low traces of organic molecules in solution, when they are adsorbed on the surface of plasmonic NPs.[13,14] SERS can also be used as a tool for probing the binding sites of the adsorbed

molecules by means of the vibrational markers arising from the molecular groups located in the vicinity, or at the surface of NPs. Herein, SERS data, as well as those from other techniques, were collected from a natural cyclic tetradecapeptide, somatostatin-14 (SST-14) (Scheme 1), adsorbed on Ag or Au NPs. We should briefly recall numerous investigations devoted to the description of the biological and medical importance of SST-14 (and its synthetic analogues), regarding its key role in the inhibition of the release of growth hormone (GH), thyroid-stimulating hormone (TSH), insulin, and glucagon.[15−17] However, the choice of SST-14 in the present work was also related to its physicochemical and structural dynamics in aqueous media. (i) Close to physiological pH, this peptide presents a cationic character thanks to the three positive charges borne by the ammonium (NH_3^+) groups located either at its N^{ter} position or on the side chain head groups of its Lys[4] and Lys[9] residues. This feature might obviously facilitate the binding of this peptide to plasmonic NPs covered by negatively charged ions. (ii) Mainly induced by the polar/apolar balance of its amino acid residues, the large size loop of SST-14 was shown to be unstructured at submillimolar concentrations,[18,19] revealing a progressive structuring trend upon increasing concentration over the millimolar range. Especially, in the 20 to 60 mM range SST-14 was shown to form high order self-assemblies, referred to as nanofibrils, spherulites and nanofibers.[20,21] Hence, SST-14 can be considered as a simple and attractive example for analyzing its possible aggregation around plasmonic NPs. Previously, the formation and time evolution of protein aggregates, referred to as "protein corona", around organic[22] and metallic[23] nanoparticles, were described. Hereafter, we use the term "corona" for referring to the aggregates formed by SST-14 around plasmonic NPs.

■ EXPERIMENTAL METHODS

SST-14 Samples. Lyophilized powder of SST-14 was purchased from Sigma-Aldrich. All samples were prepared at room temperature using purified Milli-Q water. Successive dilutions of the initial stock solutions of SST-14 prepared at 10^{-2} M (for classical Raman spectroscopy), allowed us to reach required concentrations for other experiments.

Silver Nanoparticles. A total of 300 μL of a sodium hydroxide solution (1 M) was added to 90 mL of a 6×10^{-2} M hydroxylamine hydrochloride solution. Then 10 mL from a 1.11×10^{-3} silver nitrate aqueous solution were added dropwise to the mixture under vigorous stirring. A brown silver colloid was obtained with a final pH 5.5. Ag NPs were

aged 24 h. The final NPs displayed an average diameter of 35 nm.

Gold Nanoparticles. A total of 50 mL of HAu Cl₄ 2% (by weight) was heated to boiling before addition of a variable volume (V) of Na₃-citrate 1% (by weight).[24] Au NPs with approximate diameters ranging between 15 and 150 nm (15, 50, 100, and 150 nm) were prepared by using the following citrate solution volumes: V = 1.00, 0.50, 0.20, and 0.15 mL. Finally, they were aged 2 weeks before use.

Zeta Potential Values of NPs. Electrophoretic mobility measurements were performed as described previously.[25,26] The experiments were done at 25 °C on a NanoZS instrument (Malvern Instrument Ltd., Malvern, U.K.) in DTS1060 cuvettes. The quality of the instrumentation was checked using the standard DTS1230. Intensity was always kept below 5 mA, irrespectively of the applied voltages (from 30 to 100 V), as the conductivities of the various NP samples were all below 0.5 mS·cm⁻¹, due to the low ionic strength of the buffers. The quality criteria to keep a measurement were based on (i) the zeta quality factor (signal-to-noise ratio of the frequency shift); (ii) the mean count rate that should not change throughout the duration of the data acquisition; and (iii) the quality of the phase plot (radian amplitude and frequency) and the Fourier-transformed of the phase plot. The acceptable electrophoretic mobility measurements were averaged and the standard deviation was computed. As described previously,[26] the electrophoretic mobility μ_e was converted to zeta potential ζ according to the Hückel−Onsager−Henry equation: $\zeta = (3\eta_s\mu_e/2\varepsilon_0\varepsilon_d F(\kappa R_p))$, where the electrophoretic mobility is expressed in m²·V⁻¹·s⁻¹ (or μm·cm·V⁻¹·s⁻¹), the zeta potential in V, the buffer viscosity in kg·m⁻¹·s⁻¹ (or in cP), the permittivity of free space ε_0 (8.854 × 10⁻¹² C²·J⁻¹·m⁻¹), and the medium dielectric constant ε_d = 78.54 at 25 °C. Consequently, the above equation can be simplified for the experiments performed at 25 °C as $\zeta = (21.57\eta_s\mu_e/F(\kappa R_p))$, in which the Henry's function is given by $F(\kappa R_p) = 1 + (0.5/(1 + e^{A[1-\log(\kappa R_p)]}))$, with R_p representing the particle radius, A is a numerical constant (A = 2.8 for κR_p < 10; A = 2.4 for κR_p > 10), and κ is the inverse screening length (Debye length in nm⁻¹) defined as $\kappa = (2N_A e^2 I/1000\varepsilon_0\varepsilon_d k_B T)^{1/2}$, where I (in mol L⁻¹) is the ionic strength. The inverse screening length can also be simplified at 25 °C as $\kappa = 3.27\sqrt{I}$. The zeta potential as a function of the particle distance, $\varphi(x)$, was estimated using the Debye−Hückel ionic atmosphere: $\varphi(x) = \varphi(0)e^{-\kappa x}$, with x representing the distance from the surface, considering that the zeta potential corresponds to the electric potential $\varphi(0)$ at 0.2 nm from the particle surface.
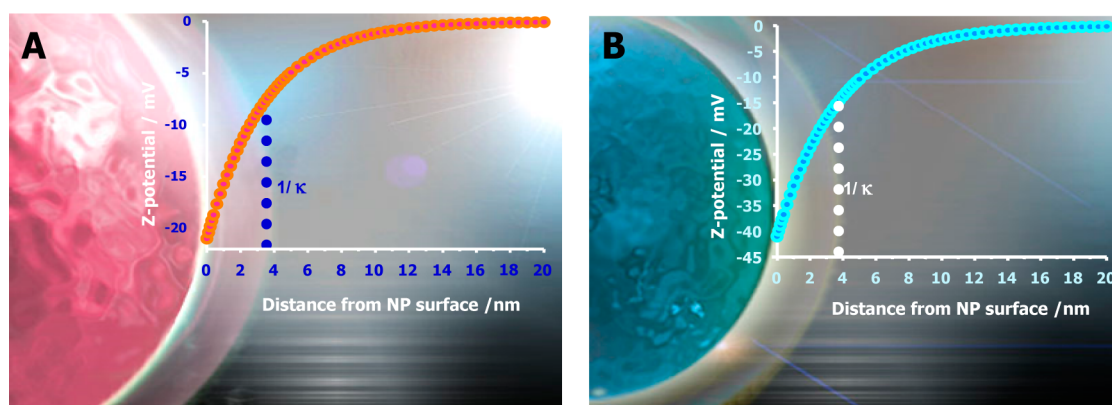

Figure 1. Variation of the zeta potential as a function of the distance from the surface of plasmonic nanoparticles. (A) and (B) refers to gold and silver colloids, respectively. Zeta potential values and distances are expressed in mV and nm, respectively.

Transmission Electron Microscopy. TEM images were taken at room temperature using a JEOL JEM-2010 with an acceleration voltage of 200 kV. The samples were prepared by depositing 10 μL of the suspension containing NPs or SST-14/NPs complexes on carbon coated Cu grids (ref G400-Cu).

Extinction Spectra. UV–vis absorption spectra of colloids were recorded from 400 to 800 nm, on a Shimadzu 3600 spectrometer by using quartz cells, 1 cm optical path. Samples were diluted 30% in Milli-Q water (volume/volume).

Surface-Enhanced Raman Spectra. Data were collected on a Renishaw Raman InVia spectrometer equipped with an electrically cooled CCD camera. Samples were excited by means of the 632.8 nm and the 785 nm lines provided by He–Ne and diode lasers with an output power of 25 and 18 mW at the sample, and a 1200 grooves/mm holographic grating. The spectral resolution was 2 cm^{-1}, with a total acquisition of 10 s for each SERS spectrum.

Classical Raman Spectra. Classical Raman spectra were collected by exciting with the 488 nm line of an Ar$^+$ laser (Spectra Physics), 50 μL of solution placed in a Suprasil quartz cell (5 mm path length). The exciting power at the sample was ~250 mW. The scattered light, collected at 90° with respect to the incident beam, was analyzed on a Jobin-Yvon T64000 spectrograph in a single mode configuration, equipped with a 1200 grooves/mm holographic grating and a holographic notch filter. A liquid nitrogen cooled CCD detection system (Spectrum One, Jobin-Yvon) was used to collect Raman data. The effective spectral slit width was set to 5 cm^{-1}.

■ RESULTS AND DISCUSSION

Main Characteristics of Plasmonic Nanoparticles. The cyclic structure of SST-14 is maintained by a disulfide (S–S) linkage between its Cys^3 and Cys^{14} residues (Scheme 1). To preserve the structural integrity of this peptide, a special attention was paid to avoid the breakdown of this S–S bond, particularly on Ag NPs, by following the procedure described recently.[24] To establish our nanofabrication protocol, the main parameters to be adjusted were (i) the metal nature and reduction protocol, and (ii) the adequate size of Ag and Au NPs for SERS experiments. Here, the SERS sensitivity was maximized by tuning the excitation wavelength over the plasmon resonance band, which depends on the size of elaborated NPs.

The zeta potential values, deduced from electrophoretic mobility measurements (see Experimental Methods for details)

in the solutions containing the adequate NPs, confirm their negatively charged coverage (Figure 1). The corresponding value estimated at the surface of Ag NPs (~−45 mV; Figure 1B) is about 2-fold lower than that corresponding to Au NPs (~−21 mV; Figure 1A). After the Stern layer, at the Debye length ($1/\kappa$) < 4 nm, corresponding to the sliding plane of the interfacial double layer, the zeta potential value increases to −15 and −8 mV in Ag and Au, respectively. This indicates that both types of colloids can exhibit on their hydrodynamic surfaces significant attractive electrostatic interaction with a positively charged molecule such as SST-14. Then, in the diffuse Gouy–Chapman layer, both types of NPs show a rapid zeta potential increase, vanishing at a distance of ~15 nm from their surface.

Nanoparticles in the Presence of SST-14. TEM images have revealed large size aggregates formed by SST-14 adsorption on plasmonic NPs (Figure 2). The charge screening of the NPs caused by the presence of the peptide should be mainly responsible for the formation of these large agglomerates. However, a net difference can be observed between the two types of aggregates. In fact, monodisperse and large size Au NPs (diameter between 90 and 100 nm; Figure 2A) and polydisperse Ag NPs (diameter between 10 and 50 nm) join together for forming the corresponding agglomerates (Figure 2B,D). Reciprocally, the adsorption of the peptide chains leads to the formation of the so-called corona around plasmonic NPs. While, a quite homogeneous peptide layer, with a depth of ~8 nm, is formed around Au NPs (Figure 2C), a variable one, of which the thickness can increase up to ~20 nm, is found around Ag NPs (Figure 2E). This effect corroborates naturally the nonidentical zeta potential values measured at the surface of Au and Ag NPs (Figure 1).

Plasmon Resonance of Nanoparticles. In a general manner, the position of the plasmon resonance band depends on the size of NPs, as well as on the type of aggregating agents (AgNO$_3$, NaCl, etc.).[27] Here, no aggregating agent was added in order to activate Ag and Au colloids. In other words, SST-14 was capable of inducing alone the aggregation of plasmonic NPs. The optimal SERS sensitivity was achieved by using large size Au NPs, consistent with a plasmon resonance redshift from 545 to 780 nm observed upon increasing peptide concentration (Figure 3A). Correspondingly, the adsorption of SST-14 on polydisperse Ag NPs prepared by means of hydroxylamine, leads to a plasmon resonance redshift from 405 to 630 nm (Figure 3B). It should be remarked that no SERS signal could be obtained on Ag colloids in the presence of citrate ions used
Figure 2. Transmission electron microscopy images of plasmonic nanoparticles. (A) A nude gold nanoparticle. (B) An agglomerate of gold nanoparticles formed in the presence of somatostatin-14, as presented with two different contrasts. (C) Zoom on a gold nanoparticle surrounded by a peptide layer. as reductor, presumably because of the competition between the citrate ion binding and the peptide chain adsorption to Ag surface.

The position of the plasmon resonance bands displayed in Figure 3, justify the choice of the excitation wavelengths 632.8 and 785 nm for recording the SERS spectra on Ag and Au colloids, respectively. Figure S1 (Supporting Information) shows two typical SERS spectra obtained in the whole spectral region (4000–400 cm^{-1}) from SST-14 adsorbed on Ag and Au colloids. The variation of the SERS intensity (as deduced from the intensity ratio between the strongest Phe marker mode at 1003 cm^{-1} and the characteristic water stretching mode at 3400 cm^{-1}) is shown as a function of the peptide concentration in Figure S2 (Supporting Information). It is worth mentioning that the shape of the corresponding curves allows getting

insight into peptide—peptide and peptide—metal interactions, thus revealing the differences between the adsorption mechanisms corresponding to different colloid types.[28,29] As a consequence, a strong peptide—peptide interaction can be deduced in the case of SST-14 adsorbed on Ag NPs.

Fingerprints of Interaction Sites Observed in Middle Wavenumber Region. The SERS spectra recorded at 10^{-6} M on Au NPs and at 5×10^{-7} M on Ag NPs are displayed in Figure 4 in the middle spectral region (1800–300 cm^{-1}), as compared to the classical Raman spectrum recorded in the bulk at a ~10^4 times higher concentration. It should be reminded that due to their conjugated π-electron systems, aromatic residues provide the major part of strong Raman markers in classical[18,19] and SERS[30] spectra.

As we have already mentioned, precaution was made to preserve the integrity of the disulfide linkage by the use of adequately prepared Ag NPs. Our nanofabrication had proved its adequacy in the case of cystine (a simple model compound formed by joining two cystines through a S—S bridge).[24] Disulfide integrity can be proved by the presence of a Raman band around 500 cm^{-1} resulting from the S—S bond stretching motion.[31] It should be also emphasized that in aqueous solution the contribution of the other modes (such as those arising from the low wavenumber bending vibrations of aromatic residues) to the Raman intensity around 500 cm^{-1}, is negligible.[31] In the present work, the presence of the band at 498 cm^{-1} confirms that the disulfide bridge is maintained on Ag NPs (Figure 4 middle). However, the weak relative intensity of this marker indicates that the S—S bond is placed quite far from the metal surface. Furthermore, except the changes observed in the Trp^8 residue characteristic mode at 1551 cm^{-1}, as well as in the aliphatic groups at 1458–1438 cm^{-1}, the SERS spectrum on Ag NPs provides globally a similar shape as that observed in the bulk (Figure 4, bottom).

On the contrary, the binding of SST-14 to Au NPs is followed by drastic changes in the wavenumbers and relative intensities of the Trp^8 Raman markers (shown by red arrows in Figure 4, top). These changes are consistent with a close contact of the Trp^8 residue with Au colloids. It should be noted that whatever the type of metallic NPs, the six characteristic Phe markers (located at ~1606, 1586, 1207, 1031, 1003, and 622 cm^{-1}),[32] remain unchanged. In other words, any close contact of the Phe residues with Au NPs can be expected based on SERS data.

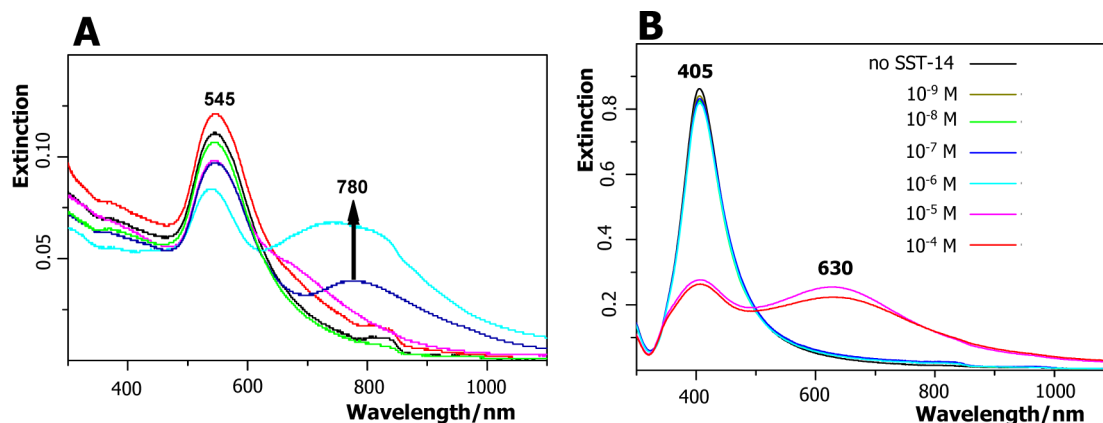

Figure 3. Extinction spectra of plasmonic nanoparticles. Data obtained from the solutions containing gold (A) and silver (B) nanoparticles at different concentrations of somatostatin-14. Color codes corresponding to different concentrations are indicated in frame (B).
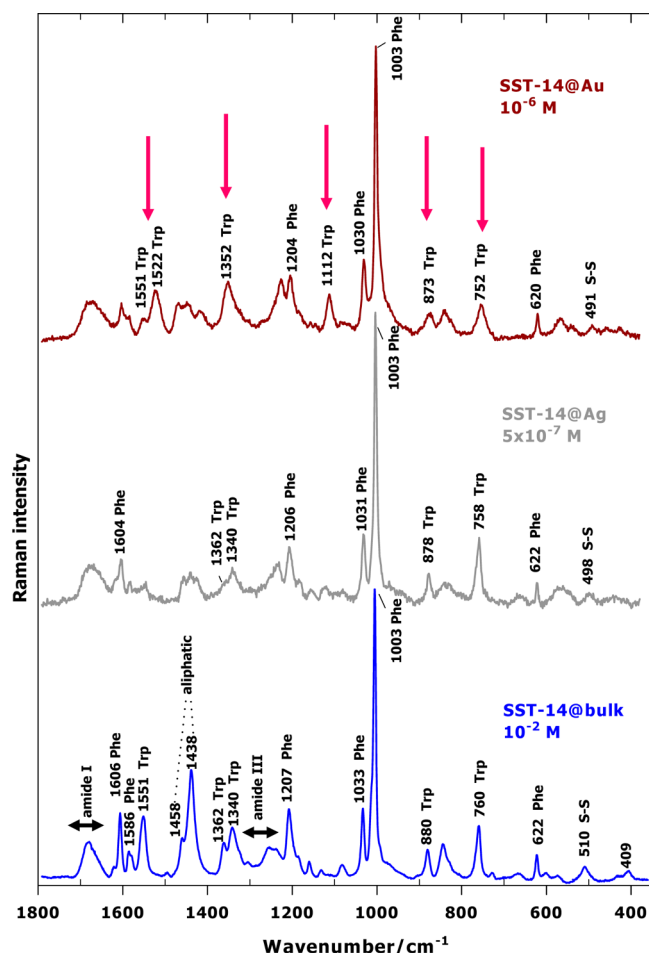

Figure 4. Middle wavenumber (1800–350 cm^{-1}) region of Raman spectra. Bottom, classical Raman spectrum of SST-14 recorded in the bulk (10^{-2} M). Middle, SERS spectrum of somatostatin-14 (5 × 10^{-7} M) adsorbed on silver nanoparticles. Top, SERS spectrum of somatostatin-14 (10^{-6} M) adsorbed on gold nanoparticles. Trp markers perturbed by the peptide adsorption on gold nanoparticles are shown by red arrows.

Fingerprints of Interaction Sites Observed in Low Wavenumber Region. The low wavenumber spectral region, that is, below 300 cm^{-1}, provides complementary information on the binding mechanism of the peptide to plasmonic NPs. This region displays the bond stretching vibrations in which the metal atom is directly involved.

Figure 5A clearly shows that nude Au NPs does not present any Raman band below 300 cm^{-1}, whereas the peptide adsorption on these particles makes appear a characteristic band peaking at 253 cm^{-1}, previously assigned to Au−N stretching vibration.[33] Putting together this observation and the SERS data in the middle wavenumber region (Figure 4, top, see preceding section for details), we conclude that the Trp^8 residue is involved in a direct interaction via charge transfer complex with Au NPs through its unique (N$_\varepsilon$) atom, as suggested in Figure 6A. Other evidence, brought about by the middle wavenumber region (Figure 4, top), confirm this particular interaction, for instance, (i) the drastic enhancement of the Raman band at 1112 cm^{-1}, ascribed to the angular bending motions located around the N$_\varepsilon$ atom of the Trp indole ring,[34] (ii) the change in the characteristic Trp Raman doublet (observed at 1362−1342 cm^{-1} in the bulk, Figure 4 bottom),

joining together for forming a single band at 1352 cm^{-1} (Figure 4 top), and (iii) the wavenumber downshifts 880 → 873 cm^{-1} and 760 → 752 cm^{-1} occurring in two other Trp bands in going from the bulk (Figure 4 bottom) to Au NPs (Figure 4 top).

In contrast, Figure 5B reveals a completely different situation for the binding to Ag NPs. Thanks to the presence of Cl$^-$ ions around silver colloids (see Experimental Methods for details), a Raman band is observed at 245 cm^{-1}, previously ascribed to Ag−Cl bond stretching mode.[35,36] In the presence of SST-14, a lower wavenumber component at ~220 nm appears, consistent with the perturbations occurring at the surface of Ag NPs by the presence of SST-14. Evidently, this interaction should be preferably of electrostatic character, that is, with one of the three cationic (NH$_3^+$) sites of the peptide. Figure 6B shows, side by side, three schemes, suggesting possible binding of the peptide through an ionic pair interaction of Ag−Cl$^-$···NH$_3^+$ type. This behavior corroborates the stronger peptide−peptide interaction occurring on Ag NPs, deduced from the variation of the SERS intensity versus peptide concentration (Figure S2, Supporting Information).

Toward Description of Peptide Corona Formed around Plasmonic NPs. The adsorption schemes suggested for individual peptides (Figure 6) can be used as a start point for analyzing the aggregation of SST-14 around metallic NPs. Following the recent spectroscopic and imaging observations in highly concentrated solutions (20−60 mM),[20,21] the first stage of SST-14 self-assembly in the bulk is a nanofibril, obtained by a side-by-side arrangement of individual peptides, stabilized by lateral amino acid interactions. Hence, the first peptide layer appearing upon aggregation around a plasmonic NP could resemble a nanofibril. Estimating by ~2 nm the largest dimension of an individual SST-14 (i.e., from its N^{ter} to the top of its loop) and considering the thickness of the peptide aggregates (TEM images, Figure 2), it can be understood that more than one peptide layer should be present in a given corona. As suggested recently,[20,21] higher order SST-14 aggregates can appear through the autoassociation of nanofibrils. Further experiments based on high resolution electron microscopy images would be necessary to confirm the abovementioned hypotheses.

■ **CONCLUSIONS**

In a recent investigation, the joint use of the middle wavenumber SERS spectra and molecular dynamics for analyzing protein−drug interactions, was emphasized.[37] Here, we pointed out the advantages of using jointly the middle and low wavenumber regions for probing the interaction sites of a cationic peptide on plasmonic NPs. In this framework, the usefulness of the data obtained from electrophoretic mobility, extinction spectra, and transmission electron microscopy, allowing determination of the charge and size of NPs, as well as the main characteristics of their complexes with SST-14, has also been highlighted.

Undoubtedly, the high affinity of SST-14 to bind to Au and Ag NPs is mainly responsible for achieving a very good signal/noise ratio in the SERS spectra recorded at very low peptide concentration. However, the differences encountered between the binding mechanisms of this peptide to the two types of plasmonic NPs are consistent with the fact that the metal nature and its ionic coverage affect the peptide binding and its subsequent aggregation process. In this work, we have also taken benefit from the presence of the corona formed by the
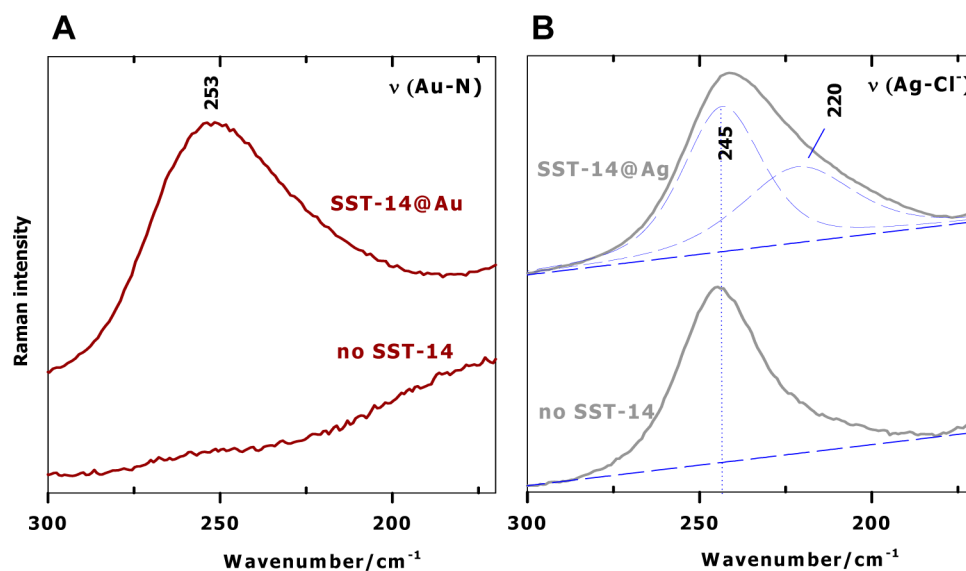

Figure 5. Low wavenumber spectral region of the surface-enhanced Raman spectra. peptide aggregation around NPs, as well as from the large size peptide/NP aggregates, in order to enhance the SERS intensity.[38] As a consequence, a cationic peptide such as SST-14, can play the role of activator in the adsorption/aggregation feedback process.

This work opens the discussion on the establishment of systematic protocols allowing controlling the coordination and binding sites of peptides and proteins on plasmonic colloids. Further investigations would confirm the applicability of the presently elaborated NPs to other cationic peptides, while other nanofabrication protocols should be suggested for facilitating the adsorption of negatively charged or neutral peptide chains.
